ABSTRACT. This paper investigates the spatial distributions of electrical current which flows inside the plasma stream generated by a magnetoplasma compressor (MPC). Two different modes of MPC operation with different gas supply scenarios have been applied in the experiments presented here. The first is the operation mode with a pulse injection of xenon into the interelectrode space, and the second is the operation mode with residual helium in the chamber and local injection of xenon directly into the compression zone. The maximum value of the electric current observed outside the MPC channel is $15 \div 20\%$ of the total discharge current. Electric current vortices were discovered in the plasma stream. The amplitude of the current in the vortices reaches $50\%$ of the total discharge current. The maximum EUV radiation power was measured in the mode of MPC operation with local xenon injection. Power in the wave range $12.2 \div 15.8\,\text{nm}$ achieves up to $16 \div 18\,\text{kw}$.

KEYWORDS: magnetoplasma compressor, toroidal current vortices, plasma discharge.

1. INTRODUCTION

This paper presents an investigation of the magnetohydrodynamic characteristics of the plasma stream generated by a magnetoplasma compressor (MPC). The distributions of the electric currents in the plasma stream were measured for different operating regimes. The maximum density of the plasma stream in the compression zone is about $10^{18}\,\text{cm}^{-3}$, and the average electron temperature along a line of view is $\sim 5 \div 7\,\text{eV}$, and the velocity of the plasma stream at the output of MPC is $\sim 10^7\,\text{cm/sec}$. The spatial distributions of the electric current in the plasma stream were measured and the spatial distributions of electromagnetic forces were investigated.

2. EXPERIMENTAL SETUP

The experiments were carried out in an MPC with a compact geometry [1, 1]. A general view of the MPC facility is presented in Fig. 1. The MPC channel is formed by coaxial copper electrodes. The outer electrode is a semitransparent multi-rod anode with output diameter 80mm, and the inner electrode is a solid cathode with output diameter 40mm. The power supply system for the MPC discharge is a bank of condensers with total capacity (90 $\mu\text{F}$) and voltage up to 25kV. The maximum value of the discharge current is 500kA and the duration of the half period is 10 $\mu\text{s}$.

Two different modes of MPC operation were investigated [2]. The first mode operates in the residual gas (helium) with pressure $2 \div 10\,\text{Torr}$. The second mode is operation with the residual gas and additional local injection of xenon directly into the compression zone (Fig. 2).

The Rogowski coil is applied for the discharge current measurements. A high voltage divider is used for the discharge voltage measurements. Numbers of local movable magnetic probes are used for an investigation of the spatial distributions of the electric current in the plasma stream. The electron density was estimated from the Stark broadening of the spectral lines. The plasma stream velocity was measured by the time-of-flight method of the plasma stream between two electric probes. Various types of AXUV diodes [3] are used for an analysis of the plasma stream radiation in the EUV wavelength range of $5 \div 80\,\text{nm}$.

Figure 1. General view of MPC experimental setup.
3. EXPERIMENTAL RESULTS

The spatial distributions of the electric current that were measured experimentally in the plasma stream for two MPC modes of operation are presented in Figs. 3 and 4. It is evident that a part of the discharge current flows into the plasma stream generated by MPC for both operation modes. The maximum value of the electric current in the plasma stream outside of the MPC channel is not more than 15% of the total discharge current. Figure 3 shows a very interesting effect when the magnetic field is pushed out from the compression zone at a distance of $5 \div 10$ cm from the output of the MPC for the first regime. The current vortex is formed at a distance of $10 \div 25$ cm. In cases when the MPC is changed from the operation regime to the mode with residual gas and additional pulse xenon injection directly into the compression zone, a vortex of electric current also forms some distance away, and displacement of magnetic field is also observed. However, the radial dimension of the displacement zone reduces and the length of the area without a magnetic field increases in comparison with the previous MPC regime.

Figure 5 presents the dependencies of the longitudinal component of the electromagnetic force, the magnetic pressure and the intensity of the radiation of the three Xe spectral lines (362.4 nm, 378.1 nm and 395 nm). This figure shows the radiation of the xenon lines in the area of maximum stream deceleration only. When the plasma stream passes through the compression zone and acceleration begins, there is no Xe radiation. At the same time, an electric current vortex is generated in the area where the plasma stream is accelerated. Thus the initial kinetic energy of the plasma stream transforms to thermal energy in the compression zone, and after that the thermal energy converts to the kinetic energy of the plasma stream and the energy of the magnetic field.

The Bernoulli equation, the total energy of the plasma stream which consists of the kinetic energy, the thermal energy and the energy of the magnetic field, has a constant value

$$\frac{v^2}{2} + \int \frac{dp}{\rho} + \frac{H^2}{4\pi \rho} = \text{const.} = U.$$

In the MPC channel, the plasma stream has kinetic energy only. The kinetic energy of the plasma stream converts to thermal energy in the compression zone, and after that the thermal energy converts to the kinetic energy of the plasma stream and the energy of the magnetic field.

This figure shows the radiation of the xenon lines in the area of maximum stream deceleration only. When the plasma stream passes through the compression zone and acceleration begins, there is no Xe radiation. At the same time, an electric current vortex is generated in the area where the plasma stream is accelerated. Thus the initial kinetic energy of the plasma stream transforms to thermal energy in the compression zone, where the plasma stream is compressed and heated. When the plasma stream passes through the compression zone, the thermal energy converts to kinetic energy and to the energy of the magnetic field. And as a result, a toroidal vortex of electric current generates in the plasma stream.
4. SUMMARY AND CONCLUSIONS

Two modes of MPC operation have been investigated. Plasma streams with density in the compression zone up to \((1 \div 2) \times 10^{18} \text{ cm}^{-3}\) are obtained. The electron temperature, estimated on the basis of the pressure balance equation, is \(60 \div 100 \text{ eV}\).

The spatial distribution of the electrical current in the plasma stream for two modes of MPC operation has been investigated. It has been shown that the maximum value of the electrical current that flows in the plasma stream generated by MPC is not more than \(15 \div 20\%\) of the discharge current in the MPC channel. The toroidal vortex of the electric current with the value of the current up to \(50\%\) of the discharge current was observed in the plasma stream. The displacement of the magnetic field from the compression zone has been discovered.

The spatial distributions of the electromagnetic force in the plasma stream are calculated. It is shown that the plasma stream is decelerated in the compression zone. The kinetic energy of the plasma stream converts to thermal energy in the compression zone. The density of the plasma stream increases up to \((1 \div 2) \times 10^{18} \text{ cm}^{-3}\) and the plasma temperature reaches \(60 \div 100 \text{ eV}\).

The radiation of the xenon spectral lines in different wavelength ranges has been observed from the compression zone. In the optimal mode of MPC operation, with local xenon injection directly into the compression zone, the maximum value of the radiation energy in the wavenumber of \(12.2 \div 15.8 \text{ nm}\) is \((5 \div 6) \times 10^{-2} \text{ J}\), and the maximum value of the power is \(16 \div 18 \text{ kW}\).
